

Standup 5: Modeling Income and Credit Scores

This week, I implemented a Random Forest classification model to analyze the relationship between income and credit score categories. The model achieved approximately 72.8% accuracy, with stronger performance for the "Standard" category and weaker performance at the extremes.

A major challenge was model interpretability. While predictive performance was acceptable, understanding why the model made certain decisions required additional analysis through feature importance metrics.

Next week, I will shift focus to payment delay analysis using non-parametric statistical methods. Documentation includes model evaluation metrics and feature importance visualizations.
